Keywords: Halochromates, Kinetics, Mechanism, Oxidation, Phosphorus acids.

Picolinium chlorochromate (PICC) in dimethylsuloxide (DMSO) oxidizes lower oxyacids of phosphorus, forming matching oxyacids with phosphorus in a higher oxidation state. The reaction shows a stoichiometry of 1:1. In relation to PICC, the response is first order. Regarding the reductants, a kinetics of the Michaelis-Menten type was noticed. Acrylonitrile does not undergo polymerization as a result of the reaction. Hydrogen ions function as catalysts for reactions. The form of the hydrogen-ion dependency is: $k_{\text{obs}} = a + b[H^+]$. Deuterated phosphinic and phenylphosphinic acids showed a significant primary kinetic isotope impact during oxidation. Nineteen different organic solvents were used to study the oxidation. The multiparametric equations of Taft and Swain were used to analyze the solvent effects. The influence of the solvent shows that the polarity of the solvent is crucial to the process. The penta-coordinated tautomer of the phosphorus oxyacid has been shown to be the reactive reductant, and it has been determined that the tricoordinated forms of phosphorus oxyacids do not take part in the oxidation process. It has been hypothesized that the rate-determining phase involves the transfer of a hydride ion.

Introduction

Inorganic salts of Cr(VI) are well-known oxidants for the organic compounds. However, these salts are rather drastic and non-selective oxidants. Further, they are insoluble in most organic solvents. Thus miscibility is a problem. To overcome these limitations, a largenumber of organic derivatives of Cr(VI) have been prepared and used in organic synthesis as mild and selective oxidants in non-aqueous solvents [1-5]. Picolinium chlorochromate (PICC) is also one of such compounds used for the oxidation of primary and secondary alcohols [6]. We have been interested in the kinetic and mechanistic aspects of the oxidation by complexed Cr(VI) species and several studies on halochromates including that of PICC, have already been reported from our group [7-10]. Further, the lower oxyacids are reported to exist in two
tautomeric forms [11-12], and it is of interest to
determine the nature and species of the oxy-acid
acid that is involved in the oxidation process.
There seems to be no report on the oxidation of
oxyacids of phosphorous by PICC, therefore we
report in this article the kinetics of oxidation of
phosphinic (PA), phenylphosphinic (PPA), and
phosphorous (POA) acids by PICC in
dimethylsulphoxide (DMSO) as a solvent. A
suitable mechanism has also been proposed.

**Experimental**

**Materials:** The phosphorous oxyacids were
commercial products and used as received. PICC was
prepared by the reported method [6] and its purity was
checked by an iodometric method and melting
point determination. Deuteriated phosphinic
(DPA) and duterated phosphorus acids (DPOA)
were prepared by repeatedly dissolving the acid
in deuterium oxide (BARC, 99.4%) and
evaporating water and the excess of deuterium
oxide in vacuum [13]. The isotopic purity of the
deuterated PA and POA, as determined from their
NMR spectra, was 93±5% and 95±5%
respectively. Due to the non-aqueous nature of
the medium, toluene-p-sulphonic acid was used
as a source of hydrogen ions. TsOH is a strong
acid and in non-polar solvents like DMSO, it is
likely to be completely ionized. Other solvents
were purified by their usual methods.

**Stoichiometry:** The oxidation of lower
oxyacids of phosphorus leads to the formation of
corresponding oxyacids containing phosphorus
in a higher oxidation state. Reaction mixtures
were prepared containing a known excess of
phosphinic or phosphorous acids. On
completion of the reaction, the amount of
phosphorous formed in the oxidation of
phosphinic acid and the residual reductant in the
oxidation of phosphorous acids were
determined by the reported method [14]. To
determine the stoichiometry of the oxidation of
PPA, a known excess of PICC was treated with
PPA and the residual PICC was determined
spectrophotometrically at 365 nm after the
completion of the reaction. The oxidation state
of Chromium in the completely reduced
reaction mixture, determined by iodometric
titration, was 3.90±0.15. The oxidation exhibited
1:1 stoichiometry and the overall reaction may,
therefore, be written as:

\[
\text{RPH(O)OH} + \text{O}_2\text{CrClO}^-\text{PicH}^+ \\
\rightarrow \text{RPH(O)(OH)}_2 + \text{O}_2\text{CrClO}^-\text{PicH}^+ (1)
\]

(R = H, Ph or OH)

PICC undergoes two-electron change.
This is following the earlier observations with
structurally similar other halochromates. It has
already been shown that both pyridinium
chlorochromate (PCC) [15] and pyridinium
fluorochromate (PFC) [16] act as two-electron
oxidants and are reduced to chromium (IV)
species determining the oxidation state of
chromium by magnetic susceptibility, ESR and
IR studies.

**Kinetic measurements:** The reactions were
studied under pseudo-first-order conditions by
keeping an excess (× 15 or greater) of the [oxy-acid] over [PICC]. The solvent was DMSO, unless specified otherwise. The reactions were studied at constant temperature (0.1 K) and were followed by monitoring the decrease in the [PICC] spectrophotometrically at 365 nm for up to 80% reaction. Pseudo-first-order rate constants, $k_{obs}$, were evaluated from linear plots ($r > 0.9990$) of log [PICC] against time. Duplicate kinetic runs showed that the rates were reproducible to within ±3%.

**Results**

*Rate laws:* The reactions were found to be first order concerning PICC. The reactions exhibited the Michaelis-Mententype of kinetics for the oxyacids (Table 1). A plot of $1/[\text{oxy-acid}]$ versus $1/k_{obs}$ is linear with an intercept at the rate-ordinate (Figure 1). This indicates the following overall mechanism (Equations 2 and 3) and the rate law (4).

Oxyacid + PICC ⇌ [complex] (2)

[Complex] → Products (3)

Rate = $k_2 K [\text{PICC}][\text{Oxyacid}] / (1 + K [\text{Oxyacid}])$ (4)

![Figure 1. Oxidation of POA by PICC: A double reciprocal plot](image)

Figure 2. Oxidation of POA by PICC: A typical kinetic run

The dependence on reaction rate on reductant concentration was studied at four different temperatures and the values of $K$ and $k_2$ were evaluated from the double reciprocal plots. The thermodynamic and activation parameters were also calculated from the values of $K$ and $k_2$, respectively, at different temperatures (Table 2 and 3). Figure 2 depicts a typical kinetic run.

**Induced polymerization of acrylonitrile/**

**Test for free radicals:** The oxidation of oxyacids, in an atmosphere of nitrogen, failed to induce polymerization of acrylonitrile. Further, the addition of acrylonitrile did not affect the rate. This indicates that one-electron oxidation, giving rise to free radicals, is unlikely in the present reaction (Table 1). To further confirm the absence of free radicals in the reaction pathway, the reaction was carried out in the presence of 0.05 mol dm$^{-3}$ of 2,6-di-t-butyl-4-methylphenol (butylated hydroxytoluene or BHT). It was observed that BHT was recovered unchanged, almost quantitatively.

**Kinetic isotope effect:** To ascertain the importance of the cleavage of the P-H bond in the rate-determining step, the oxidation of deuterated PA and POA was studied. Results showed the presence of a substantial primary kinetic isotope effect (Table 2).

**Effect of acidity:** the reaction is catalyzed by hydrogen ions (Table 4). The hydrogen ion dependence has taken the form: $k_{obs} = a + b[H^+]$. The values of $a$ and $b$, for PPA, are $9.14\pm0.49 \times 10^{-3}$ s$^{-1}$ and $17.7\pm0.81\times10^{-3}$ mol$^{-1}$ dm$^3$ s$^{-1}$ respectively at 298 K ($r^2 = 0.9918$) (Figure 3).

Discussions:

Solvent effects:

The rate constants of the oxidation, k₂, in eighteen solvents (CS₂ was not considered, as the complete range of solvent parameters was not available) were correlated in terms of the linear solvation energy relationship (LESR) of Kamlet and Taft [17] (Equation 5).

\[
\log k_2 = A_0 + p\pi^* + b\beta + a\alpha \tag{5}
\]

In this equation, \(\pi^*\) represents the solvent polarity, \(\beta\) the hydrogen bond acceptor basicities, and \(\alpha\) is the hydrogen bond donor acidity. \(A_0\) is the intercept term. The results of correlation analysis in terms of equation (5), a bi-parametric equation involving \(\pi^*\) and \(\beta\), and separately with \(\pi^*\) and \(\beta\) are given below as equations (6) – (9).

</table>

$\log k_2 = -2.97 + 1.92 \ (\pm 0.23) \ \pi^* + 0.21 \ (\pm 0.19) \ \beta + 0.32 \ (\pm 0.18) \ \alpha$ \ (6)

$R^2 = 0.8744; \ sd = 0.21; \ n = 18; \ \psi = 0.39$

$\log k_2 = -2.90 + 2.04 (\pm 0.23) \ \pi^* + 1.01 (\pm 0.19) \ \beta$ \ (7)

$R^2 = 0.8455; \ sd = 0.22; \ n = 18; \ \psi = 0.42$

$\log k_2 = -2.92 + 2.06 (\pm 0.22) \ \pi^*$ \ (8)

$r^2 = 0.8427; \ sd = 0.22; \ n = 18; \ \psi = 0.41$

$\log k_2 = -1.92 + 0.47(\pm 0.45) \ \beta$ \ (9)

$r^2 = 0.0637; \ sd = 0.54; \ n = 18; \ \psi = 0.99$

Here $n$ is the number of data points and $\psi$ is the Exner's statistical parameter [18]. Kamlet's tri-parametric equation explains $ca. 87\%$ of the effect of solvent on oxidation. However, by Exner's criterion [18] the correlation is not even satisfactory ($cf.$ equation (6). The major contribution is solvent polarity. It alone accounted for $ca. 84\%$ of the data. Both $\beta$ and $\alpha$ play relatively minor roles.

The data on the solvent effect were analyzed in terms of Swain's [19] equation (10) of cation- and anion-solvating concept of the solvents.

$log k_2 = aA + bB + C$ \ (10)

Here $A$ represents the anion-solvating power of the solvent and $B$ the cation-solvating power. $C$ is the intercept term. $(A+B)$ is postulated...
to represent the solvent polarity. The rates in different solvents were analyzed in terms of equation (10), separately with A and B and with (A + B).

\[
\log k_2 = 0.50 \pm 0.05 \, A + 2.08 \pm 0.04 \, B - 2.74 \quad (11)
\]

\[R^2 = 0.9953; \text{ sd } = 0.04; \, n = 19; \, \psi = 0.07\]

\[
\log k_2 = 0.21 \pm 0.69 \, A - 1.83 \quad (12)
\]

\[r^2 = 0.0053; \text{ sd } = 0.56; \, n = 19; \, \psi = 1.02\]

\[
\log k_2 = 2.05 \pm 0.10 \, B - 2.90 \quad (13)
\]

\[r^2 = 0.9643; \text{ sd } = 0.11; \, n = 19; \, \psi = 0.19\]

\[
\log k_2 = 1.56 \pm 0.20 \, (A + B) - 2.79 \quad (14)
\]

\[r^2 = 0.7748; \text{ sd } = 0.26; \, n = 19; \, \psi = 0.49\]

The rates of oxidation of PPA in different solvents showed an excellent correlation in Swain's equation (cf. equation 11) with the cation-solvating power playing the major role. In fact, the cation-solvation alone account for ca. 99% of the data. The correlation with the anion-solvating power was very poor. The solvent polarity, represented by (A + B), also accounted for ca. 77% of the data. In view of the fact that solvent polarity is able to account for ca. 77% of the data, an attempt was made to correlate the rate with the relative permittivity of the solvent. However, a plot of \(\log k_2\) against the inverse of the relative permittivity is not linear (\(r^2 = 0.5096; \text{ sd } = 0.39; \, \psi = 0.72\)).

**Reactive Species:**

*Reactive oxidizing species:* The observed hydrogen-ion dependence suggests that the reaction follows two mechanistic pathways, one is acid-independent and the other is acid-dependent. The acid-catalysis may well be attributed to a protonation of PICC to yield a protonated Cr (VI) species which is a stronger oxidant and electrophile (15).

\[
[O_2CrClO\text{PicH}^-] + H^+ \rightleftharpoons [HOCrOClO\text{PicH}^-] \quad (15)
\]

Formation of a protonated Cr(VI) species has earlier been postulated in the reactions of structurally similar pyridinium chlorochromate (PCC) [7] and quinolinium fluorochromate (QFC) [8].

*Reactive reducing species:* Lower oxyacids of phosphorus are reported to exist in two tautomeric forms [11,12]. The predominant species is the penta-coordinated form (A). The value [20] of the equilibrium constant, \(K_t\), in aqueous solutions, is of the order of \(10^{-12}\).

\[
RPH(O)OH \rightleftharpoons R - P - (OH)_2 \quad (A) \quad (B)
\]

Hence two alternative broad mechanisms can be formulated. Assuming in the first instance penta-coordinated tautomer (A) is the reactive reducing species, the following mechanism may be proposed which leads to the rate law (19).

\[
\text{PICC + RPH(O)OH} \rightleftharpoons [\text{complex}] \quad (17)
\]

\[
k_a \text{[complex] \rightarrow Products} \quad (18)
\]

\[
\text{Rate} = k_a \frac{[\text{Oxy-acid}]_0 [\text{PICC}]}{1 + K_t [\text{oxy-acid}]_0} \quad (19)
\]
Where $[\text{Oxy-acid}]_0$ represents the initial concentration of the oxy-acid. Equation (19) can be reduced to (20) as $1 \gg K_t$.

$$\text{Rate} = k_a K_a [\text{Oxy-acid}]_0 [\text{PICC}] / (1 + K_a [\text{Oxy-acid}]_0) \quad (20)$$

Another mechanism can be formulated assuming the tri-coordinated form (B) as the reactive reducing species.

$$K_b \text{PICC} + \text{RP(OH)}_2 \rightleftharpoons [\text{complex}] \quad (21)$$

$$k_b [\text{Complex}] \longrightarrow \text{Products} \quad (22)$$

$$\text{Rate} = k_b K_b K_A [\text{Oxy-acid}]_0 [\text{PICC}] / (1 + K_t K_b [\text{Oxy-acid}]_0) \quad (23)$$

This mechanism leads to the rate law (24), which can be reduced to (20), again acknowledging $1 \gg K_t$.

$$\text{Rate} = k_b K_b K_A [\text{Oxy-acid}]_0 [\text{PICC}] / (1 + K_t K_b [\text{Oxy-acid}]_0) \quad (24)$$

Therefore, in the plots of $1/k_{obs}$ versus $1/[\text{Oxy-acid}]$, the slope and the intercept are equivalent to the values given below. Slope $= (k_b K_b K_A)^{-1}$, intercept $= 1/k_b$, intercept/slope $= K_b K_A$.

It is thus seen that $k_2 = k_a = k_b$, which means that the rate constant for the decomposition of the complex is not affected by the reactive form of the phosphorus oxy-acid. However, $K = K_t K_b$, so that $K_b = 10^{12} K$ or $K_b$ for PPA should have a value of the order of $10^{12}$. Generally, chromium (VI) does not give rise to an extensive and highly stable series of complexes [21]. Further, the reported values [22,23] of the formation constant for the chromic acid-PPA complexes are 6.12±0.3, 11±2, and 19±4 $\text{dm}^3\text{ mol}^{-1}$. Similarly, the formation constant of complex [24] between tri-ethylamine and Cr(VI) di-peroxide derivative is 0.0014 $\text{dm}^3\text{ mol}^{-1}$. Thus the very high value of the formation constant of the present oxidant-phosphorus oxy-acid complex is improbable, and it is highly unlikely that the tri-coordinated form is involved in the oxidation process.

**Mechanism**

The absence of any effect of the radical scavenger on the reaction rate and the failure to induce polymerization of acrylonitrile point against one-electron oxidation give rise to free radicals. The presence of a substantial kinetic isotope effect confirms the cleavage of a P–H bond in the rate-determining step. A preferential cleavage of a P–H bond, in the rate-determining step, is likely in view of the relatively high bond dissociation energy of the O-H bond. The mean value of the bond dissociation energy of an O-H bond [25] is 460 kJ mol$^{-1}$, while that for a P-H bond [26] is 321 kJ mol$^{-1}$. Therefore, a hydride transfer mechanism may be proposed for the oxidation of these oxyacids. The proposed mechanism involving the hydride ion transfer in the rate-determining step is also supported by the observed major role of the cation-solvating power of the solvents.

It has already been shown that both PCC
[15] and PFC [16] act as two electron-changed oxidants and are reduced to chromium (IV) species by determining the oxidation state of chromium by magnetic susceptibility, ESR and IR studies. In the chromic acid oxidation of phosphinic acid Sengupta and Chakaldar[23] postulated the participation of tri-coordinated tautomer. However, no evidence has been presented and the author did not take into consideration the small value of Kt. However, Sharma and Mehrotra [22] reported that in chromic acid oxidation, it is not possible to point the reactive form of the compound. The formation of a phosphinium ion in the rate-determining step has been postulated by the earlier workers [22,23]. (Scheme 1).

The rates of oxidation follow the order PPA > PA > POA. The faster rate of PPA could be explained based on the stabilization of positively polarized phosphorus, in the transition state, by the phenyl group through resonance. The slower rate of POA may well be due to the electron-withdrawing nature of the hydroxyl group causing an electron deficiency at the phosphorus atom. This makes the departure of an anion more difficult. A perusal of the activation parameters in Table 3 revealed that the reaction rates are controlled mainly by the entropy of activation.

It is of interest to compare the mode of oxidation of lower oxyacids of phosphorus by pyridinium fluorochromate (PFC) [27], PCC [28] and PICC. The oxidation by PCC exhibited the second-order kinetics, first with respect to each reactant. The oxidation by PFC and PICC presented a similar kinetic picture i.e. Michaelis-Menten type of kinetics. The rate-law, acid dependence, and kinetic isotope effect are similar in both cases. In all three oxidations, excellent correlations were obtained in terms of Swain's equation with the cation solvating power of the solvents playing the major role.
Conclusion

The oxidation of lower oxyacids of phosphorus involves the hydride ion transfer in the rate-determining step, further, it is also supported by the observed major role of the cation-solvating power of the solvents.
